2 Distinguishing transgender DNA
3 methylation

4 Assam El-Osta^{1,2,3,4,5,6*}

5 Research into the epigenetic gap of gender incongruence
6 is taking us to unexpected places and a prospective study
7 on transgender people recently published in *Clinical Epi-*
8 *genetics* - “Gender Affirming Hormone Therapy induces
9 specific DNA methylation changes in blood” by Rebecca
10 Shepherd; Ingrid Bretherton; Ken Pang; Toby Mansell;
11 Anna Czajko; Bowon Kim; Amanda Vlahos; Jeffrey D.
12 Zajac; Richard Saffery; Ada Cheung; Boris Novakovic has
13 revealed some surprising results [1].

14 The major reproductive hormones, estrogen and
15 testosterone, are steroids responsible for driving the
16 development and regulation of the female and male
17 reproductive tissues. When cells are stimulated, more
18 often than not, steroid hormones recognise and bind spe-
19 cific nuclear receptors that can control gene expression.
20 Fundamental to the development and maintenance of
21 sexual phenotype, nuclear hormone receptors are ligand
22 inducible transcription factors that include members of
23 the hormone receptor family. The human estrogen recep-
24 tor (ER) is one classic example, estrogen activates the
25 translocation of ligand-inducible transcription factors
26 in the nucleus. This transactivation is functionally regu-
27 lated by nuclear proteins that influence histone modifi-
28 cations on the chromatin template that serve to regulate
29 transcription. Belonging to the same steroid hormone
30 receptor family, the androgen receptor (AR) is a hor-
31 mone-activated transcription factor that is stimulated by
32 testosterone and its metabolite, 5 α -dihydrotestosterone
33 (DHT). Undergoing conformational changes in the

cytoplasm, AR dissociates from heat shock proteins to
translocate into the nuclear compartment and bind spe-
cifically to AR sequence elements in DNA to regulate
gene transcription. Like other members of the super-
family, progesterone receptor (PR) when stimulated by
progesterone follows a path of ligand-dependent tran-
scriptional activation. The commonality here is the spe-
cific recognition of ER, AR and PR transcription factors
to bind to response elements in DNA and the involve-
ment of co-regulatory molecules that are capable of
regulating histone modifications such as acetylation and
the remodelling of chromatin to activate gene transcrip-
tion. While the shared signalling principles of nuclear
hormone receptors are known to precisely coordinate
ligand-inducible transcription factors, there is emerging
evidence that multiple hormones act in concert to effec-
tively regulate nuclear events and is thought to be central
to sexual development, skeletal muscle growth, metabo-
lism and nervous system development. Furthermore,
while sex hormones are known to interact with and influ-
ence immune response, their capacity to effect changes in
DNA methylation remains poorly understood.

In this issue of *Clinical Epigenetics*, the authors have
examined the longitudinal impact of gender affirming
hormone therapy or GAHT on differential DNA meth-
ylation by assessing leukocytes derived from blood of
individuals that identified as either, transgender women
($n=13$) or transgender men ($n=13$) [1]. The influence
of feminising and masculinising hormone therapy at 6
and 12 months were compared to baseline DNA meth-
ylation profiles of the same individuals before GAHT. The
median age at the commencement of hormone therapy
of transgender women was 29 years with an interquartile

67 range (IQR of 22–61) and the median age was 23 years
68 (IQR 21–24) of transgender men.

69 Masculinising hormone therapy comprised of trans-
70 dermal or intramuscular testosterone whereas feminising
71 hormone therapy involved estradiol and the inclusion of
72 anti-androgens comprising but not limited to proges-
73 terone. Adherence to hormone therapy was assessed by
74 immunoassay measurements of serum testosterone and
75 estradiol. Comprehensive genome-wide coverage com-
76 prised assessment of over 850,000 methylation sites.
77 The EPIC array includes probes that recognise CpG sites
78 located in gene-centric regions such as promoter regions,
79 gene bodies and distal regulatory regions. This assess-
80 ment of genomic regions revealed GAHT influenced
81 progressive changes in DNA methylation at 6 months
82 that remained or advanced at 12 months for transgen-
83 der women and transgender men when compared to
84 baseline methylation. Close examination of the longitu-
85 dinal impact emphasises divergent methylation direc-
86 tions with time. Exclusive hypomethylation clusters were
87 associated with feminising GAHT whereas unambiguous
88 hypermethylation clusters were associated with mascu-
89 linising GAHT. While this opposing methylation pattern
90 expanded after 12 months of GAHT, transient methyl-
91 ation clusters were also identified, showing consequential
92 gains of DNA methylation at 6 months and returns to
93 baseline methylation levels at 12 months. The influence
94 of GAHT on DNA methylation is clearly dynamic and
95 unmistakably complicated.

96 Interestingly, the prospective analyses highlighted pre-
97 viously unrecognised DNA methylation signatures. For
98 example, GAHT dramatically influenced immune cell
99 DNA methylation in an age-dependent and sex-specific
100 manner. Relative to baseline indices, feminising GAHT
101 reduced DNA methylation at the 3' UTR of the *VMP1*
102 gene at 6 and 12 months. Methylation robustness was
103 also observed with masculinising GAHT identifying
104 reduced methylation of the *PRR4* promoter was indeed
105 sex-specific and also considered to be age-dependent.
106 In fact, close examination of array probes in and around
107 this region confirmed reduced methylation in people
108 assigned male at birth when compared to people assigned
109 female at birth.

110 Studies in gender dysphoria and the science of GAHT
111 haven't always been inclusive. The size of the transgen-
112 der population remains for the best part—imprecise
113 and uncertain, related in part by the accuracy of cen-
114 sus data. Transgender people also grapple with barriers
115 to healthcare and the dilemma of engagement with
116 clinical care services. That inequality in fundamental
117 research presents complicated challenges understand-
118 ing health outcomes in adults receiving GAHT. While
119 the current longitudinal cohort involved a small number

120 of transgender individuals, the study did not involve
121 longitudinal age-matched cisgender representation [2].
122 Nonetheless, forging ahead without a larger prospective
123 cohort or GAHT-free cisgender representation would
124 have meant abandoning informative methylation indices
125 which the article systematically describes for transgen-
126 der women and transgender men. Due consideration to
127 statistical and power estimates, the article published in
128 *Clinical Epigenetics* remains informative.

129 The limitation of sample size aside, the authors of the
130 article identify a vast number of differentially methylated
131 sites with each one carrying valuable information. The
132 challenge now is to understand their biological function
133 in the context of autoimmune legacy and future infection
134 risk. The most direct mechanism by which DNA meth-
135 ylation could influence gene expression is altering the
136 binding sites of transcription factors. Nuclear receptor
137 inducible transcription relies on response elements that
138 are also subject to DNA methylation and could provide
139 a potential mechanism for stable transcriptional control.
140 An attractive alternative mechanism of transcriptional
141 control could also be independent of nuclear response
142 elements. Pioneering examples exist in the regulation
143 of transcription such as MeCP2, a reader protein that
144 specifically binds methylated CG dinucleotides. While
145 the functional importance of DNA methylation on the
146 nuclear receptor-signalling axis in the context of GAHT
147 remains unclear, it may serve as a code to integrate com-
148 plex pathways regulating immune response. Chromatin is
149 not only a central integrator of nuclear hormone recep-
150 tor action; chromatin is also directly influenced by DNA
151 methylation and nowhere is this complexity more evident
152 than by the action of reader proteins such as MeCP2 on
153 gene function. Indeed, it is likely that how GAHT influ-
154 ences DNA methylation mediated events, could unam-
155 biguously merge other prime candidates. For example,
156 DNA methylation is often reciprocally regulated by the
157 action of enzymes responsible for writing and erasing
158 post translational modifications on histone and non-
159 histone proteins. Indeed, the assembly of specialised
160 chromatin structures on methylated DNA could help
161 explain the capacity of GAHT to effectively regulate gene
162 behaviour. Future research to systematically pinpoint
163 the regulatory determinants may offer opportunities to
164 understand complex immune response pathways. With
165 an optimistic outlook on future research the identifica-
166 tion of methylation-dependent gene expression repre-
167 sents a first essential step to dissect the role of GAHT in
168 signaling networks.

169 Population studies are challenging, biology is compli-
170 cated and the science of GAHT epigenetics is rarely sim-
171 ple, but studies like this offers hope and deserve attention

172 that fundamental research can shift and readily pivot to
 173 translate transgender health and individual care.

REVISED PROOF

Ready to submit your research? Choose BMC and benefit from:

- fast, convenient online submission
- thorough peer review by experienced researchers in your field
- rapid publication on acceptance
- support for research data, including large and complex data types
- gold Open Access which fosters wider collaboration and increased citations
- maximum visibility for your research: over 100M website views per year

At BMC, research is always in progress.
